B16 Software Engineering
Structured Programming
Lecture 1: Software engineering

Dr Andrea Vedaldi
4 lectures, Hilary Term

For lecture notes, tutorial sheets, and updates see
http://www.robots.ox.ac.uk/~vedaldi/teach.html

B16 Part 1: Structured Programming

Software engineering principles
- Design, modularity, abstraction, encapsulation, etc.

Structured programming languages
- Interpreted (MATLAB) vs compiled (C) languages

Control flow
- Sequencing, alternation, iteration
- Functions and libraries

Data
- Data types: primitive, aggregate, and compound
- Local and global variables, parameters
- The heap and the stack

Algorithms
- Proving algorithm correctness by mathematical induction
- Time and space complexity
- Recursion

B16: Software Engineering
Four Parts

1. Structured Programming
   - Algorithms, data structures, complexity, correctness
   - Writing programs using structure programming languages

2. Object Oriented Programming
   - Object-oriented programming
   - Writing programs using object-oriented languages

3. Computer Communications and Networking
   - How devices and computers communicate, the Internet
   - Writing programs that can exchange information on a network

4. Operating Systems
   - Hardware abstraction and virtualisation
   - Writing programs that access hardware features transparently and concurrently

Texts

The C programming language, 2nd edition
Kernaghan & Ritchie

Introduction to algorithms
Cormen, Leiserson, Rivest, Stein
Lecture 1 outline

- The challenge of building software
  - The size of code

- Software engineering
  - The aims and scope of software engineering
  - Abstraction and modularity

- Software processes & their models
  - Specification, design & implementation, validation, evolution
  - Waterfall and incremental models

- Structured programming
  - Structuring programs by using abstractions in a programming language
  - Types of languages: imperative vs declarative
  - Fundamental abstractions

The “size” of software

- SLOC: number of source lines of code

```c
#include "fisher.h"
#include "gmm.h"
#include "mathop.h"
#include <stdio.h>
#include <stdlib.h>
#include <string.h>

static void
VL_XCAT(vl_fisher_encode_, SFX)
(TYPE * enc,
 TYPE const * means, vl_size dimension, vl_size numClusters,
 TYPE const * covariances,
 TYPE const * priors,
 TYPE const * data, vl_size numData,
 int flags)
{
  vl_size dim;
  vl_index i_cl, i_d;
  TYPE * posteriors;
  TYPE * sqrtInvSigma;
  posteriors = vl_malloc(sizeof(TYPE) * numClusters * numData);
  sqrtInvSigma = vl_malloc(sizeof(TYPE) * dimension * numClusters);
  memset(enc, 0, sizeof(TYPE) * 2 * dimension * numClusters);
  for (i_cl = 0; i_cl < (signed)numClusters; ++i_cl) {
    for (dim = 0; dim < dimension; dim++) {
      sqrtInvSigma[i_cl*dimension + dim] = sqrt(1.0 / covariances[i_cl*dimension + dim]);
    }
  }
  VL_XCAT(vl_get_gmm_data_posteriors_, SFX)(posteriors, numClusters, numData, 
                                            priors, 
About 50 SLOCs worth of code

```
What 130K lines of code look like
Apollo-11, 1969

The challenge of building software
The size of code
Software engineering
The aims and scope of software engineering
Abstraction and modularity
Software processes & their models
Structured programming
Types of languages: imperative vs declarative
Fundamental abstractions

Software engineering
Aim
Software engineering seeks principles and methodologies to make programs that are:
- Usable
  - Meet their requirements, including being acceptable by the users
- Dependable
  - Reliable, secure, safe
- Maintainable
  - Can be updated with minimal effort
- Efficient
  - Run as fast as possible with limited resources

Scope
Software engineering is concerned with all aspects of software production. It includes:
- Theory
  - Computability, algorithms, correctness, complexity, formal languages
- Tools and best practices
  - Specific programming languages, programming environments, developer tools to build, debug, and analyse programs
- Management
  - Processes of software creation & maintenance

Abstraction and modularity
Software systems are far too complex to be tackled as a whole. Engineers adopt a reductionist approach based on:
- Modularity
  - Decompose the system into smaller components
- Abstraction
  - Each component behaviour has a simple description, independent of the other components and of the internal implementation
- Benefits
  - Understandability
    - Complexity of individual components is commensurate to human brainpower
  - Reuse
    - The same component can be used in many applications (e.g. transistors)
  - Isolating changes
    - The implementation of a component (e.g. transistor materials) can be changed as long as the behaviour (e.g. electrical properties) does not
Abstraction and modularity

Examples

transistor

\[ I_C = \beta I_B, \quad I_E = I_C + I_B, \quad V_{EB} = 60 \text{ mV} \]

operational amplifier

\[ V_+ = V_-, \quad I_+ = 0 \text{ A}, \quad I_- = 0 \text{ A} \]

A hierarchy of increasingly-powerful abstractions

- Transistors
- Flip-flops
- Registers
- CPU

computer
virtual machine (OS)
application / interpreter

Software processes

A software process is a set of related activities that leads to the production of a software product [Sommerville].

Key activities of a software process:
**Specification**

- **Elicit requirements from users**
- **Refine requirements until they are sufficiently precise**
- **Produce a requirement specification document**

**Example**

**Elicitation**: “The program should calculate the trajectory of a lossy bouncing ball”

**Refinement**: How is the output represented? How are the initial condition specified? The required numerical accuracy? Should air resistance be accounted for? How fast must the program run?

**Requirement specification**:

- **Input**: initial position and momentum, ball radius, restitution coefficient, ...
- **Output**: simulated trajectory, 60 Hz sampling rate, $10^{-3}$ m tolerance, ...
- **Must complete simulation in 1ms**

**Design & implementation**

- **Design**
  - **Architecture** which components
  - **Data flow** how components inter-operate
  - **Components** how components work

- **Interfaces**
  - Programmatic interface
  - Text-based interface
  - Graphical interface

- **Databases**
  - Data nature and relationships
  - Storage details
  - Security

- **Implementation**
  - A team of programmers writes each component
  - Low-level design details (e.g. specific names of local variables) are left to the programmers
  - Writing functionalities for debugging are part of the implementation (e.g. unit testing)

**Verification & validation**

- **Verification**
  - Black-box (from software specification) vs white-box (from code inspection)
  - Top-down (system testing) vs bottom-up (unit/component testing)

- **Coverage of the tests**
  - Exhaustive testing is impossible
  - Pick representative examples of “normal” inputs as well as “corner cases”

- **Example**: Test a function to compute the tangent

  - normal input: $\tan(1.1)$
  - corner cases: $\tan(-\pi/2)$, $\tan(0)$, $\tan(\pi/2)$

**Evolution**

- **Cost of software evolution**
  - **Effort**: Engineers might not understand the system anymore, must study it
  - **Risk**: Changes may have unpredictable effects

- **Reengineering software**
  - **Refactoring**
    - Improve design, quality of code
  - **Rewrite** might be needed to:
    - Switch to a new, more modern basis (e.g. new programming language)
    - Scrap old design for a new one
  - Usually keep the interface or at least the functionality equivalent
Waterfall model

- Ideally, activities are distinct stages to be signed off chronologically
- In practice, activities partially overlap and interact

**Fundamental activities**
1. Specification
2. Design & implementation
3. Validation
4. Evolution

Incremental models

- Develop the software by increments, exposing them to the user and eliciting changes, and go back to incorporate them.

**Extreme programming**
- Tight requirement-implement-test loops
- Applied at different temporal scales:
  - from seconds (implement a function)
  - to months (establish high-level goals for the next software release)
- Design as you go
- Good for small high-risk/speculative projects, bad for nuclear reactors

Lecture 1 outline

**The challenge of building software**
- The size of code

**Software engineering**
- The aims and scope of software engineering
- Abstraction and modularity

**Software processes & their models**
- Specification, design & implementation, validation, evolution
- Waterfall and incremental models

**Structured programming**
- Structuring programs by using abstractions in a programming language
- Types of languages: imperative vs declarative
- Fundamental abstractions

Imperative languages

- The most common programming languages are **imperative**.
- An imperative program is a list of instructions to be executed in the specified order to solve a problem.
- Different imperative languages are characterised by different abstractions.

**Machine Code (Intel x86)**

- 0: 55
- 1: 48 89 e5
- 4: c7 45 fc 01 00 00 00
- b: c7 45 f8 02 00 00 00
- 12: 8b 45 fc
- 15: 03 45 f8
- 18: 89 45 f4
- 1b: 8b 45 f4
- 1e: 5d
- 1f: c3

**Machine Language (x86)**

- pushq %rbp
- movq %rsp, %rbp
- movl $1, -4(%rbp)
- movl $2, -8(%rbp)
- movl -4(%rbp), %eax
- addl -8(%rbp), %eax
- movl %eax, -12(%rbn)

**Machine language**'s main abstraction are mnemonics (readable names for instructions, registers, etc.)
Imperative languages

- **Abstractions** can have a massive impact on the ease of use, understandability, maintainability, power, and efficiency of programming languages.

**Machine Language (x86)**

- `pushq %rbp`
- `movq %rsp, %rbp`
- `movl $1, -4(%rbp)`
- `movl $2, -8(%rbp)`
- `movl -4(%rbp), %eax`
- `addl -8(%rbp), %eax`
- `movl %eax, -12(%rbp)`
- `movl -12(%rbp), %eax`
- `popq %rbp`
- `retq`

**C Language**

```c
int f()
{
  int x = 1;
  int y = 2;
  int z = x + y;
  return z;
}
```

---

Declarative (functional) languages

- A **declarative program** specifies the desired behaviour of the program, but now how this is achieved in term of elementary steps.

**Regular expression**

```
[a-Z]*
```

This means that the program should match any string consisting only of letters from 'a' to 'Z'. It says what the program should do.

**C language**

```c
bool f(char const * str)
{
  bool match = true;
  while (*str) {
    match &= ('a' <= *str && *str <= 'Z');
    str ++ ;
  }
  return match ;
}
```

This is a C implementation of the same program. It specifies how to solve the problem in terms of elementary steps.
Structure in imperative languages
An overview of fundamental abstractions

Data
Data types: elementary, aggregate and compound.
Variables.

Control flow
Blocks, conditionals, loops, switches.
Statements.

Procedural languages
Functions, data scoping, encapsulation, recursion.

Object-oriented programming (Part II of the course)
Attach behaviour to data.

Hello world!
Getting started with C programming

```c
#include <stdio.h>
int main(int argc, char** argv)
{
  printf("Hello, world!\n") ;
  return 0 ;
}
```

B16 Software Engineering
Structured Programming

Lecture 2: Control flow, variables, procedures, and modules

Dr Andrea Vedaldi
4 lectures, Hilary Term

For lecture notes, tutorial sheets, and updates see
http://www.robots.ox.ac.uk/~vedaldi/teach.html

Lecture 2 outline

- Control flow
  - Imperative languages
  - Goto (considered harmful)
  - Blocks, conditionals, loops
- State
  - Variable
  - Data types
  - Static vs dynamic typing
- Compiled vs interpreted language
  - MATLAB functions, subfunctions, toolboxes
  - C/C++ declaration, definition, objective, and executable files
- Practical notes
  - Clean vs obfuscated code
  - Avoid cut & paste
Control flow

An imperative program is a list of statements (instructions) to execute.

- Statements are executed sequentially.
- The program counter (PC) is a register pointing to the current instructions.
- It is incremented to move to the next instruction.

10 sleep eight hours
11 wake up
12 have breakfast

Branching statements

- Allow for non-sequential execution, conditionally on the state of the program.
- Branching is performed by resetting the program counter.

13 if today is Saturday then goto 10
14 leave home

Control flow using goto

BASIC language example:

10 i ← 0
20 i ← i + 1
30 print i, “ squared is “, i * i
35 print i, “ cubed is “, i * i * i
40 if i >= 10 then goto 60
50 goto 20
60 print “that’s all folks!”

Goto and line numbers (don’t)

To insert a line of code, one uses an intermediate line number (!)

Goto and labels (still don’t)

Labels are an abstraction of line numbers and simplify the use of goto.

- A label is just a name given to a statement in the sequence.

Structured control flow

Goto is (almost) never used. Any program can be expressed in term of three simple control structures [Böhm-Jacopini 66]:

- Blocks (sequences of executable statements)
  - { do_this ; do_that ; do_something_else ; }

- Conditionals (execute a block if a condition is true)
  - if (condition) { }

- Loops (keep executing a block until a condition remains true)
  - while (condition) { }

Spaghetti monster

Structured program

- i ← 0
- more: i ← i + 1
- print i, “ squared is “, i * i
- if i >= 10 then goto end
- goto more
- end: print “that’s all folks!”
Structured control flow

**Code blocks**
- The code is much easier to understand because each block has
  - only one **entry point at the beginning**
  - only one **exit point at the end**

**Example**
```
i ← 0
more:
i ← i + 1
if i >= 10 then goto end
print i, “ squared is ”, i*i ;
goto more
end:
print “that’s all folks!”
```

**Structured program**
```
{i
   i ← 0
   while (i < 10)
      i ← i + 1
      print i, “ squared is ”,
   }
print “that’s all folks!”
}
```

**Structured control flow: procedures**
- A way to create a software module or component is to wrap a sequence of statements in a **procedure**.

```
procedure print_n_squared_numbers(n)
{
   i = 0
   while (i < n)
      i = i + 1
      fprintf(’%d squared is %d
’,i,i*i);
   }
print(’that’s all folks!
’);
}
```

**MATLAB vs C**

C version
```
#include <stdio.h>

void print_n_squared_numbers(int n)
{
   int i = 0 ;
   while (i < n) {
      i = i + 1 ;
      printf("%d squared is ",i*i);
   }
printf("that’s all folks!\n");
}
/* the program entry point
 is called main */
int main(int argc, char **argv)
{
   printf_n_squared_numbers(10) ;
   return 0 ;
}
```

MATLAB version
```
function print_n_squared_numbers(n)
   i = 0 ;
   while (i < n) 
      i = i + 1 ;
      fprintf(’%d squared is 
’,i,i*i);
   end
fprintf(’that’s all folks!\n’);
end
```

Both MATLAB and C are imperative and procedural.
MATLAB is interpreted, C/C++ is compiled
MATLAB is dynamically typed, C/C++ is statically typed.

**Lecture 2 outline**
- **Control flow**
  - Imperative languages
  - Goto (considered harmful)
  - Blocks, conditionals, loops
- **State**
  - Variable
  - Data types
  - Static vs dynamic typing
- **Compiled vs interpreted language**
  - MATLAB functions, subfunctions, toolboxes
  - C/C++ declaration, definition, objective, and executable files
- **Practical notes**
  - Clean vs obfuscated code
  - Avoid cut & paste

Examples
- `y = tan(x) // compute the tangent of a number`
- `printf("a string") // display a string on the screen`
- `window = createWindow() // create a new window on the display`
- `destroyWindow(window) // destroy it`
Statements and the state
- Program state = program counter + content of memory
- Executing a statement changes the state
  - Updates the program counter
  - Almost always modifies the content of the memory as well
- Example
  50 * x * x + y ; // result is not remembered, no effect
  z = 50 * x * x + y ; // write the result to the variable z
- If a statement does not alter the content of the memory, it has essentially no effect
- Exceptions:
  - wasting time
  - in MATLAB, displaying a value on the screen
  - other side effects

Data types
- A (data) type specifies
  - a set of possible values
    e.g. integers in the range −2,147,483,648 to 2,147,483,647
  - what one can do with them
    e.g. create, assign, sum, multiply, divide, print, convert to float, ...
- A data type representation specifies how values are actually stored in memory
  e.g. integer is usually represented as a string of 32 bits, or four consecutive bytes, in binary notation
- This is another example of abstraction
  You never have to think how MATLAB represents numbers to use them!
- Most programming languages support several primitive data types:
  - MATLAB: numeric arrays (characters, integer, single and double precision), logical arrays, cell arrays, ...
  - C: various integer types, character types, floating point types, arrays, strings, ...

Memory and variables
- A computer’s memory is just a large array of words (strings of bits)
- Addresses
  
<table>
<thead>
<tr>
<th>Address</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>00000000</td>
<td>66 72 65 64</td>
</tr>
<tr>
<td>00000001</td>
<td>...</td>
</tr>
<tr>
<td>milesToGo:</td>
<td>001F034C</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>MEMORY (4GB)</th>
</tr>
</thead>
<tbody>
<tr>
<td>00000000</td>
</tr>
<tr>
<td>00000001</td>
</tr>
<tr>
<td>...</td>
</tr>
<tr>
<td>001F034C</td>
</tr>
<tr>
<td>1F034C</td>
</tr>
<tr>
<td>66 72 65 64</td>
</tr>
</tbody>
</table>

- The meaning depends on how it is interpreted:
  - 32 bit integer: 1718773092
  - 4 characters: “fred”
  - floating point: 1.68302e+022
- Write a 32-bit integer to memory in C
  *((int *) 0x001F034C) = 1718773092 ;
- Structured version: using a variable
  milesToGo = 1718773092 ;
- To a first approximation, a variable is just a name given to a memory address (and a data type)

Dynamic data typing
- Consider the following MATLAB fragment
  % x, y, and z are stored as 64-bit float
  x = 5 ;
  y = 10 ;
  z = x * y ;
- Each variable stores both:
  - the address of the data in memory and
  - the type of the data
- Use the MATLAB command who to get a list of variables and their types (classes):

<table>
<thead>
<tr>
<th>Name</th>
<th>Size</th>
<th>Bytes</th>
<th>Class</th>
</tr>
</thead>
<tbody>
<tr>
<td>x</td>
<td>1x1</td>
<td>8</td>
<td>double</td>
</tr>
<tr>
<td>y</td>
<td>1x1</td>
<td>8</td>
<td>double</td>
</tr>
<tr>
<td>z</td>
<td>1x1</td>
<td>8</td>
<td>double</td>
</tr>
</tbody>
</table>
Dynamic data typing

Consider the following MATLAB fragment

```matlab
% x, y, and z are stored as 64-bit float
x = 5;
y = 10;
z = x * y;
```

```
MEMORY
```

% now reassign x and z
x = 'Oxford U';
z = x * y;

Now variable x refers to
- a new memory block and
- a different data type

In MATLAB, the data type associated to a variable can be determined only at run-time, i.e. when the program is executed.

This is called **dynamic typing**

---

Overhead in dynamic data typing

In dynamic data typing each a variable is associated to both the **actual data record** as well as **metadata** describing its type.

While usually this is not a problem, in some cases the overhead may be significant.

Example: MATLAB uses about 80 bytes to store the data type descriptor.

- Storing **one array of 1 million numbers** uses 80 + 8 * 1e6 bytes (~ 7.6 MB, efficiency ~ 100%)
- Storing **1 million arrays of 1 number each** uses (80 + 8) * 1e6 bytes (~ 83 MB, efficiency ~ 9%)

---

Two operations are involved in calculating z:
- **promotion**: the string x is reinterpreted as an array of 1x8 64-bit floats
- **vector-matrix mult.**: the scalar y is multiplied by this array
In C variables must be **declared** before they can be used.

A declaration **assigns statically a data type** to a variable.

**Examples**

- `int anInteger ; /* usually 32 bits length, but implementation dependent */`
- `unsigned int anUnsignedInteger ;`
- `char aCharacter ;`
- `double afloat ;`
- `int32_t a32BitInteger ; /* C99 and C++ */`
- `int16_t a16BitInteger ;`

**Statically-typed variables**

- have a well defined type before the program is run
- incorporate constraints on how a variable can be used

Static typing allows for
- smaller run-time overhead in handling variables
- better error checking before the program is run

**Compiled vs interpreted languages**

MATLAB is an **interpreted language**
- a MATLAB program is executed by an **interpreter**
- the interpreted emulates a CPU capable of understanding MATLAB instructions
- significant overhead at run-time

C and C++ are **compiled languages**
- a C/C++ program must be translated by a **compiler**
- into an executable format before it can be executed
- no overhead at run-time
- the compiler can spot programming error violating assumptions expressed in the code
  - for example, in a statically typed language the compiler can check that operations on variables involve data of the correct types

**Example**

Compiling the following fragment generates an error because the multiplication of an integer and a pointer (see later) is not defined:

```c
int * aPointerToInt = 0 ;
int anInt = 10 ;
int anotherInt = anInt * aPointerToInt ;
```

**MATLAB: program organisation**

MATLAB procedures are called **functions**

A MATLAB function is stored in a **homonymous file with a .m extension**

```matlab
function print_ten_squared_numbers(n)
i  =  0  ;
while i < n
    i  =  i  +  1  ;
    fprintf('%d squared is %d
',i,i*i);
end
fprintf('that\’s all folks!
');
end
```

A .m file can also contain a **script**.

A script does not define a function. It is more similar to cutting & pasting code into the MATLAB prompt.
MATLAB: program organisation

MATLAB procedures are called functions.

A MATLAB function is stored in a homonymous file with a `.m` extension.

```matlab
function print_ten_squared_numbers(n)
i = 0;
while i < n
    i = i + 1;
    fprintf('%d squared is %d
', i, i*i);
end
thats_all();
end
```

MATLAB Toolboxes are just collections of functions organised in directories.

C/C++: program organisation

C/C++ explicitly support the notion of modules.

A module has two parts:
- the declaration (.h), defining the interface of the functions i.e. the function names and the types of the input and output arguments
- the definition (.c), containing the actual implementation of the functions

```c
#include "usefulstuff.h"

int main(int argc, char** argv) {
    print_n_squared_numbers(10);
    return 42;
}
```

C/C++: compiling a program

Run the compiler `cc`
Each .c file is compiled into an object file .o
This is the binary translation of a module

Run the linker, usually also implemented in `cc`
The .o files are merged to produce an executable file
### C/C++: compiling a program

- Run the compiler `cc`
  - Each `.c` file is compiled into an object file `.o`
  - This is the binary translation of a module

- Run the linker, usually also implemented in `cc`
  - The `.o` files are merged to produce an executable file

### More on declaring, defining, and calling functions

#### Declaration of the function prototype
```c
void print_n_squared_numbers(int n);
```

#### Definition of the function implementation
```c
void print_n_squared_numbers(int n)
{
    /* do something */
}
```

#### Invocation of the function
```c
print_n_squared_numbers(10);
```

- **Declaring** a function defines its **prototype** = (name of the function, type of input/output parameters)
- **Defining** a function specifies its **implementation**. The parameters are said to be **formal** as their value is not determined until the function is called.
- **Calling** a function starts executing the function body. The parameters are said to be **actual** because they are assigned a value.

### Return value(s)

- In C functions have a single output value, assigned by the `return` statement.
  ```c
  int get_awesome_number()
  {
      return 42;
  }
  ```

- In MATLAB functions have an arbitrary number of output values.
  ```matlab
  function [a,b,c] = get_many_numbers()
  a = 42;
  b = 3.14;
  c = +inf;
  return;
  end
  ```

### Lecture 2 outline

- **Control flow**
  - Imperative languages
  - Goto (considered harmful)
  - Blocks, conditionals, loops

- **State**
  - Variable
  - Data types
  - Static vs dynamic typing

- **Compiled vs interpreted language**
  - MATLAB functions, subfunctions, toolboxes
  - C/C++ declaration, definition, objective, and executable files

- **Practical notes**
  - Clean vs obfuscated code
  - Avoid cut & paste
Some practical notes

- The look *is* important
- Use meaningful **variable names**
- Use **comments** to supplement the meaning
- **Indent** code for each block/loop
- Avoid to cut and paste code
  - Use functions to encapsulate logic that can be reused
  - Cutting and pasting code leads to guaranteed disasters
    - because when you need to change the code, you need to change all the copies!
- Top-down vs bottom-up
  - **Design** top-down
  - **Code** bottom-up or top-down, or a combination

Obfuscated code (don’t)

  ```c
  char M[3], A, Z, E = 40, J[40], T[40];
  main(C)
  {for(*J = A = scanf("%d", &C);
    --
    E;
    J[ E ] = E;
    printf("._");
    for(; (A -= Z = !Z) ||
      (printf("\n|"
            , A
            = 39
            , C
            )
    ) ; Z ||
    printf ( M )
    M[Z] = Z - (E = A[J - Z]) & A
    & A ==
    ];
  }
  ```
- Can you figure out what this does?

B16 Software Engineering
Structured Programming

Lecture 3: Scope, dynamic memory, pointers, references, recursion, stack, compounds

Dr Andrea Vedaldi
4 lectures, Hilary Term

For lecture notes, tutorial sheets, and updates see [http://www.robots.ox.ac.uk/~vedaldi/teach.html](http://www.robots.ox.ac.uk/~vedaldi/teach.html)
The scope of a variable

- The **scope of a variable** is the context in which the variable can be used.
- The scope of a **local variable** is the function where the variable is defined. Usually, local variables are created when the function is entered, and destroyed when it is left.
- **Global variables** can be accessed by all functions. They are created when the program starts, and destroyed when it ends.

**MATLAB example**

```matlab
function x = myFunction(n)
    m = 10;
    x = m * n;
end

% test script
myFunction(5) % 50
m = 20;
myFunction(5) % still 50!
```

**MATLAB global variables**

- MATLAB strongly discourages the use of global variables.
- When they are really needed, they must be declared by the `global` operator.

```matlab
function x = myFunction(n)
    global m;
    x = m * n;
end

% test script
global m;
myFunction(5) % 50
m = 20;
myFunction(5) % still 50!
```

**C/C++ global variables**

- A variable is **implicitly global** if declared outside of any function.
- Question: which part of the program is responsible for initialising `m`?
- A global variable defined in a module is visible only to the functions of that module.
- To make the variable visible from other modules it must be declared in the `.h` file, exactly like functions.
- Furthermore, the `export` keywords must be used.

```c
#include <stdio.h>

int m; /* global */

int myFunction(int n) {
    return m * n;
}

/* global declaration */
export int m;

int myFunction(int n);
```

You can always use MATLAB `whos` command to check your variables:
Procedure as functions

- **Procedures** are often intended as **functions**:  
  - Then only effect of calling a procedure is to compute and return an output value.  
  - The output value depends only on the value of the input parameters.

- **Side-effects** break the function-like semantics  
  - e.g. a global variable is an implicit input/output parameter

---

**Side-effects**

- A procedure is useful only if its **behaviour is easy to predict and understand**.
- This is particularly important in **software libraries**:
  - e.g. C/C++ `math.h` (`tan`, `cos`, ...)
  - e.g. MATLAB toolboxes
- In practice, many procedures have **side-effects** beyond the simple function-like semantics:
  - reading a file, displaying a message, generating an error, ...
  - allocating and returning a new memory block
  - reading / writing a global variable
  - operating on data in the caller scope by means of references (see later)
  - ...
- A clean interface design (and documentation) is essential to control these side-effects.

---

**Memory organisation**

- A structured program organises the memory into four areas:
  1. The **code** area stores the program instructions.  
     - The OS prevents the program from changing it.
  2. The **data** (or heap) area contains **dynamically** allocated records.  
     - Implicit in MATLAB, using `malloc()` in C.  
     - It grows towards the bottom as more memory is allocated.
  3. The **stack** area is used to handle recursive procedure calls and **local variables**.
  4. The **free** area is memory not yet assigned to a particular purpose.
**Dynamic memory allocation / MATLAB**

- In MATLAB dynamic memory allocation is **implicit**.

```matlab
% allocate 80,000 bytes to store an array of 10,000 double
x = zeros(100,100);
```

**Dynamic memory allocation / C**

- In C/C++ dynamic memory allocation is **explicit**.

In C a new memory block is obtained by calling the `malloc()` function. Allocated memory must be disposed by calling `free`; otherwise the memory is leaked.

- The output of `malloc` is the **address** of the allocated memory block.

- An **address** is stored into a variable of type **pointer to T**.

```c
/* declare a pointer x to a double */
double *x;
/* allocate a double (eight bytes) and store the address in x */
x = malloc(8);
/* better: use sizeof to get the required size */
x = malloc(sizeof(double));
/* write to the memory pointed by x */
*x = 3.14;
/* free the memory once done */
free(x);
```

**Pointers and dereferencing**

- A **pointer to T** is a variable containing the address to a record of type T. Its type is denoted `T*`.

  ```c
  /* Declare and assign a pointer to double */
  double *x;
  x = malloc(sizeof(double));
  /* Dereference x to access the pointed memory */
  *x = 3.14;
  /* This changes the pointer, not the pointed data. */
  *x = 42;
  /* This crashes the program because x does not contain the address of a valid memory block anymore */
  free(x);
  ```

- The operator `*` is called **dereferencing**. It allows accessing the value pointed by the pointer.

**Null pointers**

- By convention, the memory address 0 (0x0000000) is reserved.

- A **null pointer** is a pointer with value 0 (denoted by `NULL`).

- Null pointers are commonly used to represent particular states. For example:
  - `malloc()` returns `NULL` if the requested memory block cannot be allocated because the memory is exhausted (an error condition).
  - In a linked list a `NULL` pointer may be used to denote the end of the list (see Lecture 4).

- Note that writing to a null pointer (or as a matter of fact to any address not corresponding to a properly allocated memory block) crashes the program (or worse!). For example:

```c
int *myPointer = NULL;
*myPointer = 42; /* crash */
```
Pointers can be copied:

```c
unsigned int * x = malloc(sizeof(unsigned int)) ;
unsigned int * y = x ;
```

Pointers can also point to a local variable.

```c
unsigned int a = 42 ;
unsigned int * x = &a ;
```

The operator & is called referencing. It returns the address of a variable.

Now the same data record can be accessed by using the variable or the pointer:

```c
/* these three instructions have the same effect */
a = 56 ;
*x = 56 ;
*(&a) = 56 ;
```

---

**Pass by value vs reference**

- **C++ (but not C)** can pass parameters by **reference** instead of **value**
  - Think of references as implicit pointers

```c
void swap(int *a, int *b) {
    int temp = *a ;
    *a = *b ;
    *b = temp ;
}
/* example usage */
int x = 10 ;
int y = 20 ;
swap(&x,&y) ;
/* x = 20, y = 10 */
```

Using **pointers** (C or C++).

```c
void swap(int a, int b) {
    int temp = a ;
    a = b ;
    b = temp ;
}
/* example usage */
int x = 10 ;
int y = 20 ;
swap(x,y) ;
/* x = 20, y = 10 */
```

Using **references** (C++ only)

---

**Pointers and references: why?**

- **Uses.** Pointers/references are powerful:
  - they allow a procedure to access data of the caller (e.g. `swap()`)  
  - they allow to pass data to a procedure avoiding copying (faster)
    
  E.g. think of passing a 1000-dimensional vector
  - they allow to construct interlinked data structures
    
  E.g. think of lists, trees, containers in general

- **Caveats.** Pointers/references allow **side effects**:
  - they make a procedure behaviour harder to understand
  - they make programming errors harder to find
    An error inside a procedure may affect the caller in unpredictable ways

- In **MATLAB**
  - there are (almost) no **references nor pointers**
  - it is only possible to assign or copy the **value** of variables
    Under the hood, however, all data are passed by reference. The pass-by-value semantic is ensured by sharing copies as much as possible.
Lecture 3 outline

Scope
- Local and global variables
- Modularisation and side effects

Dynamic memory and pointers
- Memory organisation, dynamically allocating memory in the heap
- Pointers, dereferencing, referencing, references
- Passing by values or reference, side-effects

Recursion
- Procedures that call themselves
- Recursion and local variables
- The stack and stack frames
- Passing functions as parameters
- Compound data types: structures

Recursion
- Recursion is one of the most powerful ideas in computer programming
- Algorithmic techniques such as divide & conquer map directly to recursion
- Many data structures are recursive (e.g. trees)
- Procedures can also be called recursively

Example: computing the factorial of \( n \)

Mathematical definition
\[
\text{fact}(n) = \begin{cases} 
1, & n = 1, \\
\text{fact}(n - 1), & n > 1.
\end{cases}
\]

Corresponding C function
\[
\text{int fact(int n)} \\
\{ \\
\quad \text{int m ;} \\
\quad \text{if (n == 1) return 1 ;} \\
\quad \text{m = n * fact(n - 1) ;} \\
\quad \text{return m ;} \\
\}
\]

Recursion and local variables
- The local variables constitute the “private” state of the function. Each execution has its own state.
- In this manner, recursive calls do not interfere with each other.
- And memory for local variable is allocated only when needed.

Recursion and the stack
- The stack is a memory area used to handle (recursive) calls to procedures.
- A stack frame is pushed on top of the stack when a procedure is entered, and popped when it is left. It contains:
  - a return location (PC)
  - to enable resuming the caller upon completion of the procedure
  - the input and output parameters
  - the local variables

Diagram:
- Code area
- Data area
- Stack area
- Stack frame
- Local variable \( m \)
- Local variable 1
- Parameter \( k \)
- Parameter 1
- Return value \( n \)
- Return value 1

Diagram:
- Stack frame
  - Local variable \( m \)
  - Local variable 1
  - Parameter \( k \)
  - Parameter 1
  - Return value \( n \)
  - Return value 1
  - Stack area
    - CODE
    - DATA
    - FREE
    - STACK
Example of recursive calls

```c
int fact(int n)
{
    int m;
    if (n == 1) return 1;
    return n * fact(n - 1);
}
```

/* example usage */

```c
x = fact(5); printf("fact(5) is \%d", x);
```

Recursion: a more advanced example

- **Multiple recursion.** A procedure can call itself multiple times.

This example paints the image region of colour `old_colour` containing the pixel \((x, y)\) with `new_colour`.

```c
const int SIZE = 256;
int im[SIZE][SIZE];

void fill(int x, int y, int old_colour, int new_colour)
{
    if (x >= 0 && x < SIZE && y >= 0 && y < SIZE) {
        if (im[y][x] == old_colour) {
            im[y][x] = new_colour;
            fill(x-1,y,old_colour,new_colour);
            fill(x+1,y,old_colour,new_colour);
            fill(x,y-1,old_colour,new_colour);
            fill(x,y+1,old_colour,new_colour);
        }
    }
    return;
}
```

Lecture 3 outline

- **Scope**
  - Local and global variables
  - Modularisation and side effects

- **Dynamic memory and pointers**
  - Memory organisation, dynamically allocating memory in the heap
  - Pointers, dereferencing, referencing, references
  - Passing by values or reference, side-effects

- **Recursion**
  - Procedures that call themselves
  - Recursion and local variables
  - The stack and stack frames

- **Passing functions as parameters**

- **Compound data types: structures**
Passing functions as parameters

A function can be passed as a parameter of another function.

In this manner, a behavior can be communicated.

Example. Consider implementing an algorithm for the numerical solution of a first order ODE:

\[ \dot{y}(t) = -y(t), \quad t \geq 0. \]

\textit{Euler method:} choose a step size \( h \) and an initial condition \( y_0 \) and then let:

\[ y(0) = y_0, \]
\[ y(hn) = -h y(h(n-1)) + y(h(n-1)), \quad n = 1, 2, \ldots, N-1 \]

MATLAB implementation:

```matlab
function y = solve(y0, h, N)
    y = zeros(1, N);
    y(1) = y0;
    for n = 2:N
        ydot = -y(n-1);
        y(n) = y(n-1) + h * ydot;
    end
end
```

\[ \dot{y}(t) = f(y(t)), \quad t \geq 0. \]

The Euler solver needs to be modified:

\[ y(0) = y_0, \]
\[ y(hn) = h f(y(h(n-1))) + y(h(n-1)), \quad n = 1, 2, \ldots, N-1 \]

To avoid writing a new program for each \( f \) pass the latter as a parameter:

```matlab
function y = solve(F, y0, h, N)
    y = zeros(1, N);
    y(1) = y0;
    for n = 2:N
        ydot = F(y(n-1));
        y(n) = y(n-1) + h * ydot;
    end
end
```

The \@ operator returns a handle to a function. A handle is similar to a pointer.

Passing functions as parameters / MATLAB

More in general, there is one ODE problem for each function \( F \):

To avoid writing a new program for each \( F \) pass the latter as a parameter:

```matlab
function y = solve(F, y0, h, N)
    y = zeros(1, N);
    y(1) = y0;
    for n = 2:N
        ydot = F(y(n-1));
        y(n) = y(n-1) + h * ydot;
    end
end
```

```
function myF(y)
    ydot = -y;
end
```

```
solve(@myF, Y0, h, N);
```

This declares a parameter \( f \).

The type of \( f \) is "pointer to a function that takes a double as input and returns a double as output".

Passing functions as parameters / C

In C one uses a pointer to a function:

```c
double myF(double y) {
    return -y;
}
```

// this is not equivalent to MATLAB version as it integrates only one step */
```c
double solve(double func(double), double y, double h)
{
    double ydot = func(y);
    return y + h * ydot;
}
```

```c
int main()
{
    int n;
    double y[200], h = 0.05;
    y[0] = 1.0;
    for (n = 1; n < 200; n++) {
        y[n] = solve(myF, y[n-1], h);
        printf("Y[%d] = %f\n", n, y[n]);
    }
}
```

Passing functions as parameters
Compound data types: structures
Custom and structured data types

- All languages support natively a number of **primitive types**
  - C/C++: `char`, `int`, `float`, `double`, ...
  - MATLAB: arrays of `char`, `int16`, `int32`, `single`, `double`, ...

- Most languages support defining novel data types. Often these are **compound types** combining primitive types.
  - C: array and structures (`struct`)
  - C++: array, structures (`struct`), and classes (`class`)
  - MATLAB: cell arrays `{}`, structures, and classes (`class`)

- **Structures** can be used to group related information together into a single data record.

- **Classes** add a behavior to structures in term of a custom set of operations that can be applied to the data (see the next lecture series).

C/C++ structures: `struct`

- In C, each new type of structure must be declared before a corresponding variable can be defined and assigned.

  **Declaration**
  ```c
  struct Complex_ {
    double re ;
    double im ;
  } ;
  ```

  **Definition and assignment**
  ```c
  struct Complex_ c ;
  c.re = 1.0 ;
  c.im = 0.0 ;
  ```

- `typedef` can be used as a shorthand.

  ```c
  struct Complex_ {
    double re ;
    double im ;
  } ;
  typedef struct Complex_ Complex ;
  ```

MATLAB structures

- A **structure** is a compound data type which comprises related data into a single entity.

- In MATLAB, a structure is defined by assigning a variable using the `.` operator.

- **Example**: create and assigns a new variable `person`:

  ```matlab
  person.name = 'Isaac' ;
  person.surname = 'Asimov' ;
  person.age = 66 ;
  person.occupation = 'writer' ;
  ```

- The variable `person` is a structure with the following fields: name, surname, age and occupation.

- Structures can contain other structures, recursively:

  ```matlab
  person.address.city = 'New York' ;
  person.address.zipCode = '12345' ;
  ```

Example: VTOL state

- VTOL state:
  - height, velocity, mass (numbers)
  - landed (bool)

- Use a single structure to store all numbers

- data encapsulation

- abstraction

- **Example**

  ```c
  typedef struct {
    double position ;
    double velocity ;
    double mass ;
    bool landed ;
  } VTOLState ;
  ```
Creating a structure

% As a local variable
VTOLState state ;
state.position = 10 ;
state.velocity = 5 ;
state.mass = 1000 ;
state.landed = false ;

% Dynamically
VTOLState * statePtr ;
statePtr = malloc(sizeof(VTOLState)) ;
statePtr->position = 10 ;
statePtr->velocity = 5 ;
statePtr->mass = 1000 ;
statePtr->landed = false ;

Note: x-> combines dereferencing and structure access. It is the same as (*x).

Passing a structure to a function

% By value
double getThrust(VTOLState state) {
    double t = getThrust(state) ;
    return t ;
}

double t = getThrust(state) ;

double t = getThrust(&state) ;

double t = getThrust(statePtr) ;
Arrays

- An array is a data structure containing a numbered (indexed) collection of items of a single data type.
- In MATLAB arrays are primitive types.
- In C, arrays are compound types. Furthermore, C arrays are much more limited than MATLAB’s.

```c
/* Define, initialise, and access an array of three integers in C */
int a[3] = {10, 20, 30};
int sum = a[0] + a[1] + a[2];

/* Arrays of custom data types are supported too */
VTOLState states[100];
for (t = 1; t < 100; t++) {
    states[t].position = states[t-1].position + states[t-1].velocity + 0.5*g;
    states[t].velocity = states[t-1].velocity + g - getThrust(states[t-1], burnRate) / states[t-1].mass;
    states[t].mass = states[t-1].mass - burnRate * escapeVelocity;
}
```

Static vs dynamic arrays in C

- This C statement defines an array a of five integers
  ```c
  int A[5];
  ```
  The size is static because it is specified before the program is compiled. What if the size needs to be adjusted at run-time?
  - The solution is to allocate dynamically the required memory:
    ```c
    int arraySize = 5;
    int *A = malloc(sizeof(int) * arraySize);
    ```
    - Note that a is declared as a pointer to an int, not as an array. However, the array access operator [] can still be used. E.g. a[1] = 2

  Pointer math: a[n] is the same as *(a + n)
  - E.g. a[0] is the same as dereferencing the pointer (*a)
  - Under the hood, the address stored by a is incremented by n * sizeof(int) to account for the size of the pointed elements

Lecture 4 outline

- Arrays
  - In MATLAB and C
  - Pointer arithmetic
- Sorting
  - The sorting problem
  - Insertion sort
  - Algorithmic complexity
- Divide & conquer
  - Solving problems recursively
  - Merge sort
  - Bisection root finding
- Linked list
  - Search, insertion, deletion
- Trees
  - Binary search trees
- Graphs
  - Minimum spanning tree
Sorting

- **Problem**: sort an array of numbers in non-decreasing order.
- There are many algorithms to do this: bubble sort, merge sort, quick sort, ...
- We will consider three aspects:
  - Describing the algorithm formally.
  - Proving its correctness.
  - Evaluating its efficiency.
- We start from the **insertion sort algorithm**

  **Input**: an array of numbers.
  **Output**: the numbers sorted in non-decreasing order.
  **Algorithm**: initially the sorted output array is empty. At each step, remove an element from the input array and insert it into the output array at the right place.

### Insertion

- The **insertion** procedure extends a sorted array by inserting a new element into it:

  ```
  % Input: array A of size ≥ n such that A[1] <= ... <= A[n-1]
  function A = insert(A, n)
  i = n
  % the invariant is true here
  while i > 1 and A[i-1] > A[i]
    swap(A[i-1], A[i])
    i = i - 1
    % the invariant is true here
  end
  end
  ``

- A **loop invariant** is a property that is valid before each loop execution starts. It is usually proved by induction. For `insert()` the loop invariant is:

  - \( A[1] \leq A[2] \leq ... \leq A[i-1] \leq A[i] \leq ... \leq A[n] \) and
  - \( A[i] \leq A[i+1] \)

### Insertion sort

- **Input**: an array \( A \) with \( n \) elements
- **Output**: array \( A \) such that \( A[1] \leq A[2] \leq ... \leq A[n] \)

  ```
  function A = insertionSort(A, n)
  i = 1
  % the invariant is true here (A)
  while i < n
    i = i + 1
    A = insert(A, i)
    % the invariant is true here (B)
  end
  end
  ``

- **Loop invariant**: the first \( i \) elements are sorted: \( A[1] \leq A[2] \leq ... \leq A[i] \)

- **Proof** by induction

  - **base case** (A) \( i = 1 \): \( A[1] \) is sorted
  - **inductive step** (B) \( i \geq 1 \): at iteration \( i \) the `insert()` procedure sorts \( A[1], ..., A[i] \) provided that \( A[1], ..., A[i-1] \) are sorted. The latter is given by the invariant at iteration \( i - 1 \).
**Task:** sort 5 4 1 2 3

**Insertion sort: example**

<table>
<thead>
<tr>
<th>insert(2)</th>
<th>insert(5)</th>
</tr>
</thead>
<tbody>
<tr>
<td>5 4 1 2 3</td>
<td>1 2 4 5 3</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>insert(3)</th>
<th>insert(4)</th>
<th>insert(5)</th>
</tr>
</thead>
<tbody>
<tr>
<td>4 5 1 2 3</td>
<td>1 4 5 2 3</td>
<td>1 2 4 5 3</td>
</tr>
</tbody>
</table>

**Algorithmic complexity**

- **time complexity** of an algorithm is the maximum number of elementary operations \( f(n) \) required to process an input of size \( n \). Its **space complexity** is the maximum amount of memory required.

- It often suffices to determine the order of the complexity \( g(n) \): linear \( n \), squared \( n^2 \), polynomial \( n^k \), logarithmic \( \log(n) \), exponential \( \exp(n) \), ... We say that the order of \( f(n) \) is \( g(n) \), and we write \( f(n) = O(g(n)) \), if:

\[
\exists \alpha, n_0 : \forall n \geq n_0 : f(n) \leq \alpha g(n)
\]

- **Example: insertion sort**
  - The size of the input is the number \( n \) of elements to sort.
  - The space complexity is \( O(n) \) as the algorithm stores only the elements and a constant number of local variables.
  - The time complexity of `insert()` is \( O(m) \) as the while loop is executed at most \( m \) times. The time complexity of `insertionSort()` is \( O(n^2) \) because

\[
\sum_{m=1}^{n} m = \frac{(n+1)n}{2} = O(n^2)
\]

**Divide and conquer**

- **Divide and conquer** is a **recursive strategy** applicable to the solution of a wide variety of problems.

- The idea is to split each problem instance into two or more smaller parts, solve those, and recombine the results.

- Some of the best known and most famous (and useful) algorithms are of this form, notably quicksort and the Fast Fourier Transform (FFT).
Complexity of divide and conquer

- Assume that the cost of splitting and merging a subproblem of size $m$ is $O(m)$ (linear) and that the cost of solving a subproblem of size $m = 1$ is $O(1)$.

Given a problem of size $n$, at each level $O(n)$ work is done in order to split & merge or solve subproblems. Since there are $\log_2(n)$ levels the total cost is $O(n \log_2 n)$.

### Merge sort

The merge sort algorithm sorts an array $A$ by divide and conquer:

- **Split**: divide $A$ into two halves $A_1$ and $A_2$.
- **Merge**: iteratively remove from the beginning of the sorted $A_1$ and $A_2$ the smallest element and append it to $A$.
- **Base case**: if $A$ has one element only it is sorted.

```plaintext
function A = mergeSort(A)
    n = length(A)
    if n == 1 then
        return A
    end
    k = floor(n / 2)
    A1 = A(1:k)
    A2 = A(k+1:end)
    A1 = mergeSort(A1)
    A2 = mergeSort(A2)
    return merge(A1, A2)
end

function A = merge(A1,A2)
    i1 = 1, i2 = 1
    while i1 <= m1 and i2 <= m2
        if A1[i1] <= A2[i2]
            A[i1+i2-1] = A1[i1], i1 = i1 + 1
        else
            A[i1+i2-1] = A2[i2], i2 = i2 + 1
        end
    end
end
```

### Insertion vs Merge Sort

The two sorting algorithms have different complexities:

- insertion: $O(n^2)$
- merge: $O(n \log(n))$

Plotting time vs size in loglog coordinates should give a line of slope:

- $2$ for insertion sort
- $\sim 1$ for merge sort

This is verified experimentally in the figure.
**Root finding**

- **Problem**: find a root of a non-linear scalar function \( f(x) \), i.e. a value of \( x \) such that \( f(x) = 0 \).
- **Assumption**: \( f(x) \) is a continuous function defined in the interval \([a, b]\); furthermore, \( f(a)f(b) < 0 \).
- The **bisection algorithm** is a divide and conquer strategy to solve this problem.

```python
def bisect(f, a, b):
    m = (a + b) / 2
    if abs(f(m)) close to zero
        return m
    if f(m) * f(a) > 0
        return bisect(f, m, b)
    else
        return bisect(f, a, m)
```

**Lecture 4 outline**

- Arrays
  - In MATLAB and C
  - Pointer arithmetic
- Sorting
  - The sorting problem
  - Insertion sort
  - Algorithmic complexity
- Divide & conquer
  - Solving problems recursively
  - Merge sort
  - Bisection root finding

**Linked lists**

- A limitation of arrays is that inserting an element into an arbitrary position is \( O(n) \).
- This is because existing elements must be shifted (moved in memory) in order to make space for the new one.
- **Linked lists** solve this problem by using pointers:

```c
/* List element datatype */
typedef struct ListElement {
    struct ListElement *next;
    double value;
} ListElement;

/* List datatype */
typedef ListElement List;
```

- In C a list data type could be defined as follows:

```c
/* List element datatype */
typedef struct ListElement {
    struct ListElement *next;
    double value;
} ListElement;

/* List datatype */
typedef ListElement List;
```

**Inserting an element into a linked list**

- To **insert** an element into a list, use pointers to create a “bypass” at cost \( O(1) \).

```c
/* Insert an element in a list */
void insert(ListElement *prev, ListElement *element) {
    element->next = prev->next;
    prev->next = element;
}
```

**Example usage**

```c
/* Create an empty list */
List list;
list->next = NULL;
/* Insert at the beginning of the list */
insert(&list, element);
/* Create an element */
ListElement eElement = malloc(sizeof(ListElement));
eElement->next = NULL;
eElement->value = 42.0;
```
Removing an element from a linked list

To insert an element into a list, use pointers to create a "bypass" at cost $O(1)$.

Example usage

```c
/* Remove the element after previous */
ListElement * removed ;
removed = remove(prev) ;
/* Do not forget to release the memory if needed */
if (removed != NULL) {
  free(removed) ;
}
```

Binary tree

- Each node in a binary tree has one left child and one right child.
- There are no backward links (no cycles).

Example C data type
Similar to a linked list:

```c
typedef struct Node_ {
  struct Node_ *left ;
  struct Node_ *right ;
  double value ;
} Node ;
```

Depth first traversal
This algorithm visits recursively all the nodes in a tree.

```c
function visit(node)
  if node == NULL then return
  visit(node.left)
  visit(node.right)
  print(node.value)
end
```

Binary search tree

- A binary search tree is a binary tree such that the value of each node is
  - at least as larger as the value of its left descendants
  - smaller all the values of its right descendants
- Its main purpose is to support the binary search algorithm.
Binary search algorithm

**Problem**: find a node with value \( x \) in a binary search tree.

The **binary search algorithm** searches for \( x \) recursively, using the **binary search tree property** to descend only into one branch every time.

```matlab
function node = binarySearch(node, x)
if node == NULL return NULL
if node.value == x return node
if x > node.value return binarySearch(node.right, x)
else return binarySearch(node.left, x)
end
end
```

The cost is \( O(h) \) where \( h \) is the depth of the binary tree.

Typically \( h = O(\log n) \), where \( n \) is the number of nodes in the tree. Hence the search cost is \( O(\log n) \), sub-linear.

Compare this with the \( O(n) \) cost of searching in an array or a linked list.

---

Graphs

An **(directed) graph** is a set of vertices \( V \) and edges \( E \subset V \times V \) connecting the edges. An **undirected graph** is a graph such that for each edge \((u,v)\) there is an opposite edge \((v,u)\).

% MATLAB representation
edges = [1 2 2 3 4 5 5 6 2 3 6 4 5 6 8 7 2 3 6 4 5 6 8 7 1 2 2 3 4 5 5 6] ;

An alternative representation of a graph is the **adjacency matrix** \( A \). \( A \) is a \( n \times n \) matrix such that \( A(u,v) = 1 \) if, and only if, \((u,v) \in E\).

\[
A = \begin{bmatrix}
0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\
1 & 0 & 1 & 0 & 1 & 0 & 0 & 0 \\
0 & 1 & 0 & 1 & 0 & 0 & 0 & 0 \\
0 & 0 & 1 & 0 & 1 & 0 & 0 & 0 \\
0 & 0 & 0 & 1 & 0 & 1 & 0 & 1 \\
0 & 1 & 0 & 0 & 1 & 0 & 1 & 0 \\
0 & 0 & 0 & 0 & 1 & 0 & 1 & 0 \\
0 & 0 & 0 & 0 & 1 & 0 & 1 & 0
\end{bmatrix} ;
\]

A **spanning tree** is a subset of the edges forming a tree including all the nodes.

A **minimum spanning tree** (MST) is a spanning tree such that the sum of the edge weights is minimal.

A famous algorithm to compute the MST is explored in the tutorial sheet.

---

Minimum spanning tree

Consider a **weighed undirected graph** with non-negative weights on the edges:

A **spanning tree** is a subset of the edges forming a tree including all the nodes.

A **minimum spanning tree** (MST) is a spanning tree such that the sum of the edge weights is minimal.

A famous algorithm to compute the MST is explored in the tutorial sheet.
Concept summary

Software engineering processes
- Specification, design & implementation, validation, evolution
- Waterfall and extreme programming

Software engineering tools
- Abstraction and modularity
- Procedures
- Variables, data type, scoping
- Dynamic memory allocation
- Pointers, references
- Recursion, stack, stack frames
- Pointers to functions
- Compound data types

Data structures and algorithms
- Complexity and correctness
- Arrays, lists, trees, graphs
- Sorting, searching, numerical problems

Exam questions? See tutorial sheet to follow.
